Abstract

A classical precursor to a full quantum dynamics for causal sets has been formulated in terms of a stochastic sequential growth process in which the elements of the causal set arise in a sort of accretion process. The transition probabilities of the Markov growth process satisfy certain physical requirements of causality and general covariance, and the generic solution with all transition probabilities non-zero has been found. Here we remove the assumption of non-zero probabilities, define a reasonable extension of the physical requirements to cover the case of vanishing probabilities, and find the completely general solution to these physical conditions. The resulting family of growth processes has an interesting structure reminiscent of an "infinite tower of turtles" cosmology.

I. INTRODUCTION

The causal set approach to quantum gravity posits that the deep structure of spacetime is a locally finite partially ordered set [1]. One of the key open questions is a formulation of a quantum dynamics for causal sets. As a preliminary step towards such a formulation, one can define a *classical* stochastic dynamics for causal sets in terms of a sequential growth process in discrete stages, each of which involves the addition of a new element to a causal set obtained from the previous stage. In this context, the dynamical law is an assignation of probabilities to each such transition from every finite causal set to its possible 'children' in accordance with certain physical principles inspired by the continuum notions of general covariance and causality [2].[1] Ref. [2] finds the most general solution for the transition probabilities subject to these principles *and* the additional assumption that none of the transition probabilities vanish. Thus the solution is generic but not the most general one.

The causal sets which arise from the generic classical sequential growth models are reasonably well understood. For example, there is significant evidence indicating that they do not produce 'manifoldlike' causal sets [4]. It is of interest to know whether the picture changes significantly if we allow vanishing transition probabilities. The quantum theory of causal sets is expected to arise from a decoherence functional (or quantum measure) defined on sets of histories (causal sets). In some appropriate limit (say after coarse graining to achieve decoherence), one expects to get probabilities which obey a Kolmogorov sum rule, and there is no reason to expect that none of these will vanish. Thus it is important to know if there is any drastic effect which arises from the case of vanishing probabilities.

In this work we extend the considerations of ref. [2] to the general case in which the transition probabilities are required merely to be non-negative rather than positive. We will see that the general dynamics which results can be regarded as a sequence of different copies of the generic dynamics described in ref. [2], each being a 'turtle' in an infinite (temporal) tower of turtles[2] . This has been investigated earlier by Joohan Lee [5]. In our treatment

[1] The dynamics is classical in that no allowance is made for quantum interference between possible distinct transitions from any causal set to its children. A quantum dynamics would be expressed in terms of a *quantum measure*, or *decoherence functional*, which generalizes the notion of probability measure to allow for interference of distinct possibilities. [3]

[2] This is in reference to a popular legend about and old woman who, at the end of a lecture by a famous

we assume some familiarity with the terminology and proofs of ref. [2].

The outline of the paper is as follows. We extend the physical principles of discrete general covariance and Bell causality to the case of vanishing transition probabilities in section II. These principles, in conjunction with the Markovian and internally temporal nature of the growth process [2], restrict the dynamical law in certain important ways. We derive these restrictions in section III. In section IV we show that these restrictions taken together allow an explicit characterization of the most general classical dynamics describing a growth process consistent with the physical principles mentioned above. Section V contains our conclusions, and a few useful lemmas are proved in the Appendix.

II. PHYSICAL REQUIREMENTS ON THE DYNAMICS

As in ref. [2], consider $\mathcal{P}$, the poset of all (isomorphism equivalence classes of) finite causal sets (causets) wherein if a causet can be formed by accreting a single element to a second causet, then the former (the 'child') follows the latter (the 'parent') in $\mathcal{P}$ and the relation between the causets is a link (a relation not implied by transitivity). A sequential growth process corresponds to a path (i.e. a series of transitions from one causet to another) in $\mathcal{P}$, starting from the empty causet. Recall that a link may correspond to more than one distinct transition (the number of distinct transitions are the number of inequivalent embeddings of the parent as a partial stem of the child, where two embeddings are equivalent if related by an automorphism of the child; a partial stem is a sub-causet which contains its own past). A *dynamical law* is defined to be an assignation of transition probabilities (i.e. real numbers in [0,1]) to each such distinct transition for every link of $\mathcal{P}$. We shall require that the dynamical law be consistent with the principles of general covariance and Bell causality as well as the Markov sum rule defined below in sections A–C. As noted in ref. [2], the dynamics, by virtue of its formulation as a sequential growth process, automatically incorporates the property of internal temporality (which simply means that no new element can be born to the past of an existing element of any parent).

As in ref. [2], we set the probability q_0 of forming the single element causet (a 1-chain)

scientist, attempts to argue that the Earth is really flat and rests on the back of an infinite tower of turtles.

to unity.

A. General Covariance

A dynamical law is defined to be generally covariant iff,
(i) The transition probabilities for distinct transitions associated with the same link in $\mathcal{P}$ are identical.
(ii) If γ is any path through $\mathcal{P}$ which originates at the empty set and terminates at a causet C, the product of transition probabilities along its links is the same as for any other path from the empty set to C.

For any generally covariant dynamics, we shall refer to the product of transition probabilities along the links of a path connecting the empty set to a causet C as the *specific probability of formation* of C. [3]

For any assignation of transition probabilities consistent with general covariance, we define a *virtual* causet as one whose *specific probability of formation* vanishes. Thus any path from the empty set to a virtual causet contains at least one link with zero transition probability. All causets which are not virtual are called *real*. Virtual causets (and hence, their descendants) are never formed in the growth process. This is the reason that our definitions of Bell causality and the Markov sum rule below pertain only to real parents. Since only specific probabilities of formation are of interest, two dynamical laws which generate the same set of specific probabilities of formation will be referred to as *equivalent*. We restrict our considerations in the remainder of this section to generally covariant dynamics.

B. The Markov Sum Rule

We impose the same requirement as in ref. [2], except that we demand it only of real parents. Thus, we require that the sum of the full set of transitions issuing from a given *real*

[3] This is contrast to the *total* probability of formation of C defined in ref. [2]. The latter is obtained by multiplying the specific probability by the number of inequivalent natural labellings of C [2]. Note that even the total probability of formation lacks covariant meaning, in that it refers to the probability of forming a particular finite causet after a specific stage of the growth process. Physically meaningful probabilities can be extracted from the sequential growth dynamics by the measure it assigns to cylinder sets of unlabeled causets, as described in ref. [7].

causet is unity. (The full set of transitions constitutes one for each choice of partial stem of the parent. The coefficients in the sum rule of ref. [2] arise when multiple partial stems result in the same child causet.)

C. Bell Causality

As mentioned above, Bell causality is only defined for *real* parents. Let C be a real parent and C_1 and C_2 be two of its children. Let B be the union of the precursor sets for the two transitions. (Recall that a precursor set is the past of the new element whose introduction forms the child causet C_1 or C_2.) Clearly there is a path in $\mathcal{P}$ starting from the empty set, ending at C and passing through B. Since C is real so is B.

Let B_1 and B_2 be the causets defined by adding an element to the future of the corresponding precursor sets in B and let $P(C \to C_i), P(B \to B_i)$ be the transition probabilities for the transitions $C \to C_i, B \to B_i$, $i = 1, 2$. In ref. [2], Bell causality was formulated as

$$\frac{P(C \to C_1)}{P(C \to C_2)} = \frac{P(B \to B_1)}{P(B \to B_2)}. \tag{2.1}$$

This equation was meant to capture the idea that events occurring in some part of a causet should be influenced only by the portion of the causal set lying to their past. Equation (2.1) is only sensible when all transition probabilities are non-vanishing as in ref. [2]. We seek a generalization of this equation to the case of vanishing transition probabilities (i.e. when one or more of the children in (2.1) are virtual).

Let $P(C \to C') = 0$ for some transition from a real parent C to its child C'. Then a natural condition inspired by the idea alluded to just after equation (2.1) would be to forbid *all* transitions from real parents which involve the same (isomorphism class of) precursor set as in $C \to C'$. Since the transition from the empty set to the 1-chain has probability $q_0 = 1$, it would follow from such a condition that no antichain to antichain transition could be virtual. As we shall see in 6(b) of the proof of Lemma 2 in section III, the general solution to such a dynamics is that of ref. [2] in which the t_k can be zero.

Our aim is to provide as general a dynamical law as possible, following the spirit of the conditions imposed in ref. [2]. In particular, we would like to allow for the vanishing of any of the transition probabilities, including those of the antichain to antichain transitions.

A natural set of conditions which allows this and serves as a reasonable generalization of equation (2.1) may be arrived at by the following qualitative discussion.

The formulation of (2.1) may be thought to involve two distinct ingredients:
(a) The idea that there is a propensity for a transition to occur depending solely on the nature of the transition, i.e. the precursor set involved. This is incorporated in (2.1) by requiring that the transitions $C \to C_i, B \to B_i$ have the same precursor sets for each of $i = 1, 2$.
(b) The implication of the Markov sum rule that the net probability of formation of all possible children from a real parent is fixed and equal to unity. This forces (2.1) to be an equality of *ratios* of probabilities rather than probabilities themselves.

Viewed in terms of (a) and (b), a transition probability could vanish due to two distinct reasons: (1) the transition is intrinsically forbidden so that all transitions involving the same precursor set are also virtual or (2) there are so many competing siblings that they "take away the entire available probability" and drive the transition probability for the transition in question to zero. The consequences of this viewpoint are as follows. Consider, as before, the real causet C and its ancestor B. Every precursor set in B is also a precursor set in C. Hence for every birth in B there is a birth in C, but since C is larger than B, it has more children than B. Clearly, if $P(B \to B_1) = 0$ then C_1 must also be virtual since C_1 has even more competing siblings than B_1. On the other hand, if $P(C \to C_1) \neq 0$, then B_1 must also be real, since B_1 has even fewer siblings than C_1. The relative propensity of the birth of C_2 with respect to that of C_1 is then well defined as the ratio of the two transition probabilities, and may be taken to quantify the relative propensity of the birth B_2 with respect to that of B_1. In the case that both C_1 and C_2 are virtual, the relative propensity of their births is ill defined. The vanishing of $P(C \to C_i), i = 1, 2$ may be because C_1 and C_2 have too many competing siblings. The corresponding children B_1, B_2 of B have fewer competing siblings and hence it is possible that either or both these children are real.

As a result of this qualitative discussion, we formulate the Bell causality condition in terms of $C, C_i, B, B_i,\ i = 1, 2$ (which have been defined just before equation (2.1)) as follows:
(i) If all four transition probabilities are non-vanishing, Bell causality is defined by (2.1).
(ii) If $P(B \to B_1) = 0$, then $P(C \to C_1) = 0$. If $P(B \to B_2) = 0$ then $P(C \to C_2) = 0$.

(iii) If $P(C \to C_1) = 0$, $P(C \to C_2) \neq 0$, then $P(B \to B_1) = 0$, $P(B \to B_2) \neq 0$
(iv) If $P(C \to C_1) = 0$ and $P(C \to C_2) = 0$ then nothing can be inferred about $P(B \to B_1)$ and $P(B \to B_2)$.

Note that if the transition probabilities vanished only because the transition in question was intrinsically forbidden, we would obtain that $P(C \to C_i) = 0$ iff $P(B \to B_i) = 0$, $i = 1, 2$ which would in turn imply (i)–(iii) above and a *stronger* condition than (iv). In the remainder of this work we use (i)–(iv) as our definition of Bell causality. In addition we freely make use of the fact that the Bell causality conditions (i)–(iv) hold when B is replaced by any subcauset of C which contains the union of the precursors of the two transitions as a partial stem. That this is so can easily be verified for any assignment of transition probabilities consistent with general covariance as defined above.

III. SOME IMPLICATIONS OF THE PHYSICAL REQUIREMENTS

A few key consequences on sequential growth dynamics, of general covariance, Bell causality and the Markov sum rule, are derived in this section.

Lemma 1: Let the j-antichain to $j+1$-antichain transition probability q_j be such that $q_j > 0$ for $j = 1..n$. Then for $J \leq n$, the gregarious transition from any real parent of cardinality J has probability q_J. (Recall the gregarious transition is that in which the new element arises unrelated to any of the elements of the parent causet.)
Proof: Clearly, we need consider parents which are not antichains. Let such a real parent be A_0 with cardinality J. Refer to Fig. 1. The causets B_j are the gregarious children of the A_j. The D_j are parents of the A_j, as shown schematically in the diagram. The transition probabilities between various pairs of causets are as labeled. Since A_0 is real, general covariance (referred to henceforth as g.c.) implies that $a_0 \neq 0$. Suppose $x_0 \neq 0$. Then B_0 is real and g.c. implies that $b_0, w_0 \neq 0$. Now employ Bell causality (henceforth referred to as b.c.) to compare the transition probabilities w_0 and x_1 with a_0 and b_0 respectively, where a disconnected element of A_1 acts as a spectator. (Recall a spectator is an element of the parent causet which does not lie in the precursor set of either of the transitions in question.) Since both a_0 and b_0 are non-vanishing, along with w_0, b.c. (iii) forces x_1 to be non-zero as

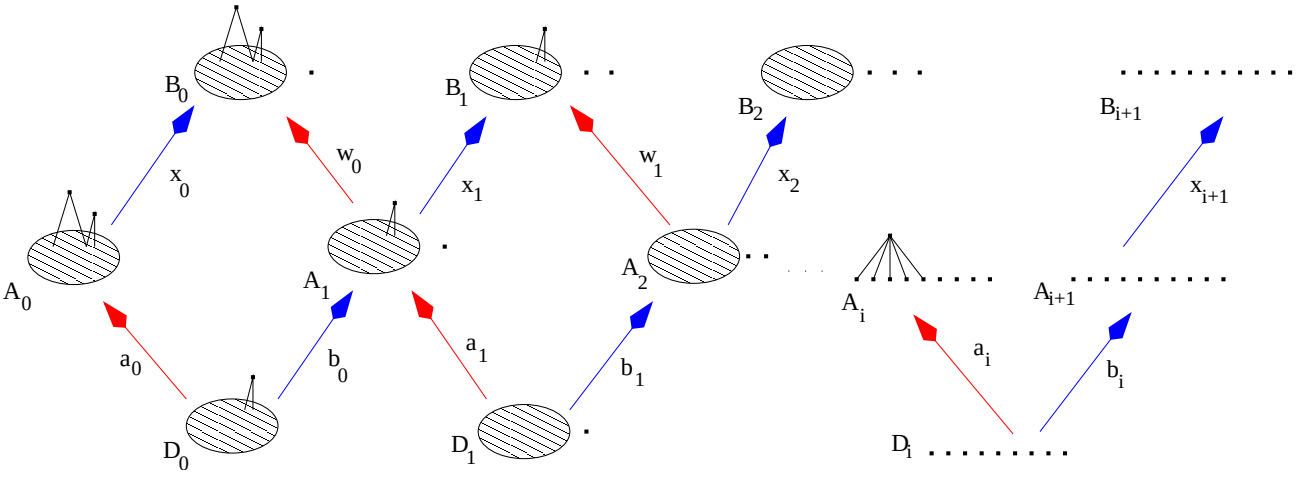

FIG. 1: All "gregarious child" transitions have probability q_J

well. Thus we may use b.c. (i) to prove that $x_0 = x_1$ as in ref. [2] (simply consider the b.c. (i) condition $\frac{b_0}{a_0} = \frac{x_1}{w_0}$ along with the g.c. condition $a_0 x_0 = b_0 w_0$). This means that B_1 is real. Since D_1 and A_1 must be real, and $a_1 \neq 0$, we can repeat the argument with A_1 in the place of A_0, and proceed rightwards across the figure.

Clearly, as in ref. [2], the process terminates for i such that: A_i has only one maximal element with non empty past, A_{i+1} is the J antichain, B_{i+1} is the $J+1$ antichain and D_i is the $J-1$ antichain. Then b.c. and g.c. imply that $x_0 = q_J$.

Above we assumed that $x_0 \neq 0$. To complete the proof, we show by contradiction that this is so. Thus suppose $x_0 = 0$. Then

(a) Suppose A_1 is real. $\Rightarrow b_0 \neq 0$. Then g.c. implies that $w_0 = 0$. Then b.c. (iii) implies that $x_1 = 0$. (Again, the disconnected element of A_1 acts as the spectator. Since $w_0 = 0$, only $x_1 = 0$ is consistent with b.c. (iii).) Further since A_1 is real, $a_1 \neq 0$ and we can repeat the argument with A_1 as the new A_0, asking now if A_2, which is the new A_1, is real. In this manner we can progress rightwards across the figure (assuming the A_j are real, c.f. case (b) below)

(b) Suppose A_1 is virtual. Since A_0 is real, we have that D_0 is real and hence $b_0 = 0$. Then we can not proceed rightwards across the figure since b.c. does not apply for virtual parents. But since D_0 is real we can choose D_0 to be our new A_0, with $b_0 = 0$ now taking the role of $x_0 = 0$, and repeat the argument (by asking again if the new A_1 is real). Note that this recursive argument must eventually end with case (a). As a 'worst case', this recursion

will eventually arrive at the 2-chain for A_0, whose only corresponding A_1 is the 2-antichain, which we know is real even for $n = 1$ (since $q_1 > 0$).

This procedure will terminate with some final choice of real A_0 with cardinality K, $2 \leq K \leq J$, such that A_0 has only one maximal element with a nonempty past, D_0 is the $K-1$ antichain, A_1 is the K antichain, and B_1 is the $K+1$ antichain. Then x_1 will be q_K, $K \leq J \leq n$, which is non-zero. But from (a) above $x_1 = 0$, which is a contradiction. This completes the proof of the Lemma.

Lemma 2: Let the antichain to antichain transition probabilities $q_1, .., q_n$ all be > 0. Then the most general sequential growth dynamics to stage n furnishes probabilities of formation of causets of cardinality $\leq n+1$ in accordance with equation (12) of ref. [2],

$$\alpha_n = \frac{\sum_{l=m}^{\varpi} \binom{\varpi - m}{\varpi - l} t_l}{\sum_{j=0}^{n} \binom{n}{j} t_j}$$

in which the coupling constants $t_k, k = 1..n$ are such that $t_k \geq 0$, or equivalently in accordance with equation (7) of ref. [2],

$$\alpha_n = \sum_{k=0}^{m} (-)^k \binom{m}{k} \frac{q_n}{q_{\varpi - k}}$$

with

$$\sum_{l=0}^{n} (-)^{n-l} \binom{n}{l} \frac{1}{q_l} \geq 0 \; .$$

Proof: Consider a sequential growth dynamics consistent with b.c., g.c. and the Markov sum rule. It is straightforward to repeat the considerations of section IV of ref. [2] *for real parents*. Here we briefly repeat the arguments, taking into account the possibility of vanishing transition probabilities.

(1) Lemma 1 holds so that any gregarious transition from a J element real parent has transition probability $q_J, J \leq n$. (Lemma 1 is the analog of Lemma 2 in ref. [2]).

(2) *Claim*: The analog of Lemma 3 in ref. [2] holds for real parents. Thus each transition probability α_m of stage $m \leq n$ from a *real* parent has the form

$$\alpha_m = q_m \sum_{i=0}^{m} \frac{\lambda_i}{q_i} \tag{3.1}$$

where λ_i are integers *only* depending on the transition in question.

Proof by induction: Equation (3.1) is easily verified for stages 0 and 1. In particular stage 1 always has one real parent and the above form for the α_1 holds. Assume (3.1) holds for stage $k-1 < n$. Consider a bold transition probability β_k of stage k from some real parent C. (Recall the timid transition is the one in which the new element arises to the future of the entire parent causet. A bold transition is any save the timid transition.) For any such causet, there exists a real parent B at stage $k-1$ such that the bold and gregarious transitions from C are in b.c. with appropriate ones from B. B can be constructed by removing from C a maximal element which is not in the precursor set for the bold transition. It is easy to see that g.c. implies that B is real if C is real. Then b.c. (i & iii) gives $\frac{\beta_k}{q_k} = \frac{\alpha_{k-1}}{q_{k-1}} \implies \beta_k = q_k \sum_{i=0}^{k-1} \frac{\lambda_i}{q_i}$ irrespective of whether the bold child of C is virtual or not. The Markov sum rule ensures that the timid child transition probability, γ_k is given by $\gamma_k = 1 - \sum_j \beta_{kj} = 1 - q_k \sum_{i=0}^{k-1} \sum_j \frac{\lambda_{ij}}{q_i}$ where j labels the possible bold transitions. As in ref. [2] this expression can be put in the form (3.1) by setting $\lambda_i = -\sum_j \lambda_{ij}, i < k$ and $\lambda_k = 1$.

(3) In transitive percolation *all* causets are real, save the special cases when $p = 0$ or $p = 1$. From ref. [2] we know that, for transitive percolation, $q_n = q^n$, where $q = 1 - p$. The case of $p = 1$ is disallowed by assumption, because in that case all q's vanish. The case $p = 0$ makes all $q_n = 1$, yielding an infinite antichain with probability 1. In the general case $\{\lambda_i\}$ for any transition from a real parent can be obtained from a comparison of $\alpha_k = q_k \sum_{i=0}^{k} \frac{\lambda_i}{q_i}$ ($k \leq n$) with α_k for transitive percolation just as in ref. [2] and we get the same answers as in ref. [2] namely

$$\alpha_k = \sum_{i=0}^{m} (-)^i \binom{m}{i} \frac{q_k}{q_{\varpi - i}} \tag{3.2}$$

where ϖ is the cardinality of the precursor set for the transition and m is the number of its maximal elements. (Note that this formula also gives probabilities consistent with transitive percolation when $p = 0$, namely that $\alpha_k = 1$ when $m = 0$, and 0 otherwise.)

(4) *Claim*: In order that for all transitions from real parents the transition probabilities $\alpha_k \in [0, 1]$, it suffices that each timid transition probability for every real parent is ≥ 0, which is in turn guaranteed if the timid transition probability from the k-antichain is ≥ 0

for all $k \leq n$. [4]

Proof: The proof of this statement is identical to that of ref. [2] restricted to real parents, save that each reference to a non-gregarious transition probability being positive is replaced by the statement that it is non-negative. In order to use our definition of b.c. in the proof, it suffices to note (as in (2) above) that for every bold transition from a real parent C at stage k ($2 \leq k \leq n$), there is a real parent B of C which contains the precursor set for the transition. Since q_k and q_{k+1} are both non-zero, our b.c. (i–iii) is equivalent to the b.c. formula used in the proof, where now the α can vanish.

(5) From (4) it follows, in an identical manner to the considerations of ref. [2], that the transition probabilities $\alpha_k, k \leq n$ from real parents of size k are of the form

$$\alpha_k = q_k \sum_{l=m}^{\varpi} \binom{\varpi - m}{\varpi - l} t_l \tag{3.3}$$

with q_k expressible in terms of t_k as

$$\frac{1}{q_k} = \sum_{l=0}^{k} \binom{k}{l} t_l. \tag{3.4}$$

As in ref. [2] the 'coupling constants' t_i can be freely chosen subject to the conditions $t_0 = 1, t_i \geq 0, 1 \leq i \leq n$.

(6) *Claim*: The transition probabilities for transitions from real parents given by the formula (3.3)–(3.4) with $t_j \geq 0, n \geq j \geq 1, t_0 = 1$, satisfy the physical requirements.

Proof: The proof is obtained simply by restricting the proof of section IV D of ref. [2] to real parents. We briefly describe how the results of ref. [2] apply here.

(a) General Covariance: Assign transition probabilities to *all* links (till stage n) in $\mathcal{P}$ according to the formula (3.2) or (3.3).[5] It is easily verified that for any path from the empty set to a causet C of cardinality $|C| \leq n+1$, the product of transition probabilities, apart from the overall factor $\prod_{j=0}^{|C|-1} q_j$, is a product of factors which are in one to one correspondence with elements of C such that the factor corresponding to the element x only depends on the

[4] Note that the k-antichain, $k \leq n+1$ is real since there is a path from the empty set to the k-antichain comprising only of antichains and the transition probability for the ith link is $q_i > 0$.

[5] Note that these transition probabilities are non-negative and identical for all transitions corresponding to the same link in $\mathcal{P}$. Hence such an assignation is consistent and defines a dynamical law.

past of x in C. Hence this product is path independent. If this product $\neq 0$, then C is real, otherwise it is virtual.

(b) Bell Causality: Restrict equation (3.2) to real parents. Then the transition probability for any birth depends, apart from a factor of q_k, only on the precursor set for the transition. As in ref. [2], this implies that b.c. (i) holds. It also implies that if any transition probability vanishes *all* births involving the same precursor set are virtual. Thus the dynamics satisfies a stronger version of b.c. than we require (see the comment at the end of section II). In this regard, note that b.c. (iv) did not come in to our derivation of the general dynamical law. Thus b.c. (i–iii), in the presence of general covariance and the Markov sum rule, implies a stronger causality condition that that expressed in b.c. (iv). (Though the situation changes when we allow the gregarious transition probabilities to vanish, and our weaker notion of b.c. becomes important in that context.)

(c) Markov Sum Rule: The proof in ref. [2] goes through without any change. The proof applies to *any* parents and we can simply restrict the proof to real parents.

Lemma 3: Let n be the smallest number for which the n-antichain to $n+1$-antichain transition probability q_n vanishes. Then: (a) There are no real gregarious children at stage j, $j \geq n$. (b) At stage n the only real children are timid children.

Proof:

(a) Again consider Fig. 1. Let A_0 be a real parent of cardinality $\geq n$ and assume that B_0 is its real gregarious child. Hence $a_0, x_0 \neq 0$. As in the proof of Lemma 1, using g.c. and b.c. (iii), it is easy to see that all the causets of Fig. 1 must be real. But these causets include the $j+1$ antichain, $j \geq n$. Since $q_n = 0$, there is a path (solely consisting of antichains) from the empty causet to the $j+1$ antichain which has specific probability $= 0$. Hence the $j+1$ antichain is virtual. This yields the desired contradiction. Hence B_0 cannot be real.

(b) Let C be a real parent (of cardinality n) at stage n. Consider the b.c. relation involving any bold child C_b of C and the gregarious child C_g of C. Let the precursor of $C \rightarrow C_b$ be C^{pre} and the relevant (timid and gregarious) children of C^{pre} be C_t^{pre}, C_g^{pre}.

Clearly, there is a path in $\mathcal{P}$ from the empty set through C^{pre} to C. Hence, since C is real, so is C^{pre}. Let us further assume that C_b is real. The same reasoning implies that C_t^{pre} is real. Then we have that

$P(C^{pre} \to C_t^{pre}) \neq 0$, $P(C \to C_b) \neq 0$.

Let the cardinality of C^{pre} be K ($K < n$ since C_b is bold). Then Lemma 1 implies that $P(C^{pre} \to C_g^{pre}) = q_K \neq 0$. Also (a) above together with the fact that C is real, implies that $P(C \to C_g) = 0$.

But this assignment of transition probabilities is in contradiction with b.c. (iii). Hence C_b cannot be real. (Note that with C_b virtual, b.c. (iv) is satisfied.) Hence the only real children produced at stage n are timid children.

Implications of Lemma 3: To describe the implications of Lemma 3 and for our subsequent considerations, it is useful to define the notion of a *C-timid* causet as follows. We shall say that a causet C' is *timid with respect to a causet* C, or that C' is *C-timid*, if $C' \supset C$ and every element in $C' \setminus C$ is to the future of every element of C.

Now, let n be the minimum stage at which $q_n = 0$ and let there be P real (non-isomorphic) parents at stage n formed as a result of sequential growth. Denote these as $C_{j,n}$, $j = 1, .., P$. By Lemma 3, only the timid transition is allowed at stage n. This means that at any subsequent stage the new element added must be to the future of the entirety of $C_{j,n}$. If not, a real growth process could be envisaged such that the child at the nth stage was not timid. *Thus, every real causet formed as a result of growth after stage n is $C_{j,n}$-timid for some unique j* (the uniqueness follows from Lemma A3 in the Appendix).

IV. THE GENERAL SOLUTION

In this section we derive the most general solution to the dynamics which satisfies the physical requirements of section II. The derivation uses the results of section III and Lemmas A1, A2 and A3 proved in the Appendix. We shall present our derivation in the form of two Lemmas 4A and 4B and a Remark. Their import is as follows.

Let $\mathcal{P}_{C_{j,n}}$ be the subposet of $\mathcal{P}$ which contains $C_{j,n}$ and all $C_{j,n}$-timid causets for a fixed j (we have defined $C_{j,n}$ at the end of the previous section above). We define a dynamical law *relative* to $\mathcal{P}_{C_{j,n}}$ to be an assignation of probabilities to links in $\mathcal{P}_{C_{j,n}}$. Such a dynamical law will be said to satisfy the physical conditions of section II *relative* to $\mathcal{P}_{C_{j,n}}$ iff

(a) the transition probabilities for distinct transitions associated with the same link in $\mathcal{P}_{C_{j,n}}$ are identical and the product of transition probabilities along any path in $\mathcal{P}_{C_{j,n}}$ starting

from $C_{j,n}$ to a causet C in $\mathcal{P}_{C_{j,n}}$ depends only on C.

(b) b.c. as defined in section II holds among causets in $\mathcal{P}_{C_{j,n}}$.

(c) the sum of transition probabilities for all $C_{j,n}$-timid children of any real parent in $\mathcal{P}_{C_{j,n}}$ is unity, where reality is defined with respect to paths in $\mathcal{P}_{C_{j,n}}$ starting from $C_{j,n}$.

Lemmas 4A and 4B show that in order to find the most general dynamical law consistent with the conditions of section II, it suffices to find the most general dynamical law relative to $\mathcal{P}_{C_{j,n}}$ which satisfies the physical principles of section II relative to $\mathcal{P}_{C_{j,n}}$, for each j separately. Remark 1 shows that the latter assignation of transition probabilities is in correspondence with a growth process from the empty set. As we shall see, by applying Lemmas 4A, 4B and Remark 1 iteratively, we shall be able to derive the general solution to the dynamics in $\mathcal{P}$.

Let $\mathcal{S}_n$ be a dynamical law for causets till stage n (i.e. the maximum size of children is $n+1$) which is specified as follows. Let the transition probabilities till stage $n-1$ be assigned in accordance with (3.2) or (3.3). As in the last paragraph of the previous section, let $q_n = 0$ and let $C_{j,n}, j = 1..P$ be the real non-isomorphic parents of size n. Further, let the timid transition from each $C_{j,n}$ occur with unit probability and every other transition at stage n with probability zero.

Lemma 4A: Let $\mathcal{S}$ be a dynamical law whose restriction up to stage n is $\mathcal{S}_n$. If $\mathcal{S}$ is consistent with g.c., the Markov sum rule and b.c. then an equivalent dynamical law [6] exists such that

(a) at stage $r \geq n$ transition probabilities for all transitions to causets which are not timid with respect to any $C_{j,n}$ vanish.

(b) g.c., the Markov sum rule and b.c. as defined in section II hold.

Proof: Since the causets described in (a) are virtual by Lemma 3, Lemma A1 ensures that we may define an equivalent dynamical law $\mathcal{S}'$ by setting the transition probabilities of (a) to zero. (b) is trivially true for $\mathcal{S}'$ from Lemma A1.

Lemma 4B: Let $\mathcal{S}$ be an assignment of transition probabilities (i.e. numbers in [0,1]) to

[6] See IIA for a definition of equivalent dynamical laws.

links in $\mathcal{P}$ such that

(a) $\mathcal{S}$ coincides with $\mathcal{S}_n$ to stage n.

Beyond stage n:

(b) transition probabilities for all transitions to causets which are not timid with respect to any $C_{j,n}$ vanish.

(c) $\mathcal{S}$ restricted to each $\mathcal{P}_{C_{j,n}}$ provides a dynamical law relative to $\mathcal{P}_{C_{j,n}}$ which satisfies the principles of section II relative to $\mathcal{P}_{C_{j,n}}$ for each j separately.

Then $\mathcal{S}$ is completely specified by (a)–(c) (i.e. (a)–(c) ensure that every link in $\mathcal{P}$ is assigned a unique number in $[0, 1]$) and is consistent with the physical principles of section II.

Proof:

Claim 1: $\mathcal{S}$ is completely specified by (a)–(c).

Proof: Transition probabilities from any causet of size $\leq n$ are specified by $\mathcal{S}_n$. Any causet of size $> n$ is either $C_{j,n}$-timid for some j or not timid with respect to any $C_{j,n}$.

If the latter then Lemma A2 shows that its only offspring are non-timid with respect to any of the $C_{j,n}$ and (b) specifies the transition probabilities. If the former, then Lemma A2 ensures that it is not $C_{k,n}$-timid for any $k \neq j$. Its children are either $C_{j,n}$-timid in which case (c) specifies the transition probabilities or, using Lemma A2, non-timid with respect to any $C_{k,n}, k = 1..P$ in which case (b) specifies the transition probabilities.

Claim 2: If (a)–(c) hold, $\mathcal{S}$ is generally covariant.

Proof: From Lemma A2 and the consistency of the dynamics of Eqns. (3.2) and (3.3) with g.c., $\mathcal{S}_n$ is clearly consistent with g.c. Hence g.c. needs to be checked only for causets of size $> n+1$. If the causet is not timid with respect to any $C_{j,n}$, then by (b) every path to it has at least one link with zero transition probability. Hence such paths satisfy g.c. If the causet is $C_{j,n}$-timid, Lemma A2 shows that every path to it is such that

(i) it passes through $C_{j,n}$.

(ii) it does not pass through any causets of cardinality $> n$ which are not timid with respect to any $C_{k,n}$, $k = 1..P$, nor through any $C_{k,n}$-timid causets, $k \neq j$ thus implying that it must pass through only $C_{j,n}$-timid causets after stage n.

Since $\mathcal{S}_n$ is consistent with g.c., (i) and (ii) in conjunction with (c) show that paths to

$C_{j,n}$-timid causets are consistent with g.c.

Claim 3: If (a)–(c) hold, $\mathcal{S}$ is consistent with the Markov sum rule.
Proof: It is easy to see that $\mathcal{S}_n$ is consistent with the Markov sum rule. Hence we only need to check it for real parents of size $\geq n+1$. Such parents must be $C_{j,n}$-timid for some j. As discussed before, Lemma A2 implies that its children are either $C_{j,n}$-timid or not timid with respect to any $C_{k,n}, k = 1..P$. (b) ensures that the latter do not contribute to the sum rule and hence (c) ensures that the Markov sum rule is obeyed.

Claim 4: If (a)–(c) hold, $\mathcal{S}$ satisfies Bell causality.
Proof: Clearly $\mathcal{S}_n$ to stage $n-1$ is consistent with b.c. since it is just the dynamical law of eqns (3.2) or (3.3). So we need to check b.c. with regard to real parents of size $\geq n$.

Case A) Real parents of size n: The only such causets are $C_{j,n}$, each of which has a single real child. Let C_1 and C_2 be children of $C_{j,n}$ for some j. There are 2 cases:
(i) C_1 is timid and C_2 is virtual: Clearly there is no b.c. with offspring of any smaller causet $D \subset C_{j,n}$. Let $D \supset C_{j,n}$ be some real parent with children D_1 and D_2 such that D_1, D_2 enjoy a b.c. relation with C_1, C_2 (our notation is such that D_1 has $C_{j,n}$ as its precursor set). Since C_2 is an ancestor of D_2, Claim 2 ensures that D_2 is virtual. As can be checked, this fact ensures that b.c. is satisfied.
(ii) C_1 and C_2 are virtual: b.c. is only non-trivial for offspring of $D \supset C_{j,n}$. Since C_1, C_2 are ancestors of D_1, D_2 respectively, Claim 2 ensures that D_1, D_2 are virtual and b.c. is satisfied.
Case B) Real parents of size $> n$: The only real parents of size $> n$ are $C_{j,n}$-timid. Fix j and let C be a real $C_{j,n}$-timid parent with children C_1 and C_2. There are 3 cases:
(i) C_1 is $C_{j,n}$-timid, and C_2 is not $C_{j,n}$-timid: Note that C_2 cannot be $C_{k,n}$-timid for any $k = 1..P$ by Lemma A2. Hence C_2 is virtual. Obviously the union of precursor sets is either $C_{j,n}$ itself or is $C_{j,n}$-timid. In the former case it is easy to check that (a) ensures that b.c. is satisfied. In the latter case C_1 and C_2 are in a b.c. relation with appropriate children D_1 and D_2 of some real causet D which contains $C_{j,n}$ as a partial stem. From Lemma A3, since D is real, D_1 is $C_{j,n}$-timid and D_2 is not $C_{j,n}$-timid and hence virtual. For $D \subset C$, g.c. (i.e. Claim 2) ensures D_1 is real if C_1 is real and hence b.c. is satisfied. (If C_1 is virtual then b.c. (iv) is an empty condition.) If $D \supset C$, then D_2 is virtual (as argued above). Further, since

C_1 is an ancestor of D_1 in our definition of b.c. , Claim 2 ensures that D_1 is virtual if C_1 is virtual and that C_1 is real if D_1 is real. Thus b.c. holds.
(ii) C_1 and C_2 are not $C_{j,n}$-timid: Thus C_1 and C_2 are virtual and b.c. says nothing about transitions from $D \subset C$. For $D \supset C$, $D_1 \supset C_1$ and $D_2 \supset C_2$ so that g.c. (i.e. Claim 2) ensures that D_1, D_2 are virtual and hence b.c. holds.
(iii) C_1 and C_2 are $C_{j,n}$-timid: b.c. is with children of D which contain a $C_{j,n}$-timid precursor set as a partial stem. Lemma A3 implies that D and its children D_1, D_2 are also $C_{j,n}$-timid.[7] Note that Lemma A2 implies that if a causet is $C_{j,n}$-timid it cannot be $C_{k,n}$-timid for $k \neq j$. Thus b.c. holds by (c).

From the above it follows that if (a)–(c) hold then $\mathcal{S}$ is consistent with b.c. This completes the proof of Lemma 4B.

Remark 1: Any dynamical law relative to $\mathcal{P}_C$ for some causet C, which satisfies the physical principles of section II relative to $\mathcal{P}_C$ is in correspondence with a growth process satisfying b.c., g.c. and the Markov rule and which starts from the empty causet. The correspondence is that every causet C' of the latter defines the causet $C'' = C \cup C'$ of the former, with every element of C' being to the future of C in C''. This remark is easily verified by inspection.

The Final Picture: An iteration of Lemma 4 and Remark 1 yields the following picture. The formation of any real causet is through a series of growth phases, each of whose transition probabilities are given by eqns. (3.2) or (3.3). A real causet formed at the end of such a growth stage will be called a *branch point causet*. Such a causet heralds a new phase of growth, with new values of the coupling constants. The transition probabilities in this new stage are given by the same formulas (3.2) or (3.3), with a completely new set of coupling constants q_n or t_n (these can be freely chosen; for example, we could choose them to depend on the previous branch point causet in some way), and the ϖ and m are interpreted ignoring the presence of the previous branch point causet. Every branch point causet $C_{\{(j_k,n_k),(j_{k-1},n_{k-1})..(j_1,n_1)\}}$ is labeled by a set of ordered pairs of natural numbers $\{(j_k, n_k), (j_{k-1}, n_{k-1})..(j_1, n_1)\}$.

[7] In the degenerate case where $D_1 = D_2$ are the timid child of $C_{j,n}$, and D is $C_{j,n}$ itself, the conclusion remains, since these are all in $\mathcal{P}_{C_{j,n}}$.

The notation signifies that $C_{\{(j_k,n_k),(j_{k-1},n_{k-1})..(j_1,n_1)\}}$ grew from the empty causet as a result of k phases of independent growth. Call the causets which arise from each phase of independent sequential growth as *turtles*. (i.e. a turtle is the difference between adjacent branch point causets.) The first stage of growth, characterized by $q_0 = 1, q_i > 0, i = 1..n_1-1$, resulted in a set of real turtles $C_{(j_1,n_1)}$ each of size n_1. Next, q_{n_1} vanished. Choosing a fixed j_1, the growth of the second set of turtles commenced, each new point being to the future of the entirety of $C_{(j_1,n_1)}$, and hence in correspondence with a sequential growth in which $C_{(j_1,n_1)}$ is replaced by the empty set. The second set of turtles were fully formed when the effective n_2 antichain to $n_2 + 1$-antichain transition probability, $q_{n_2}^{(j_1,n_1)}$, vanished. The third set of turtles' growth commenced from the parent $C_{\{(j_2,n_2),(j_1,n_1)\}}$ such that every new element was added to the future of $C_{\{(j_2,n_2),(j_1,n_1)\}}$ and so on. Thus any real causet formed in the growth process consists of turtles stacked one on top of another (see footnote 2).

V. CONCLUSIONS

The generic class of classical sequential growth dynamics derived in ref. [2] excluded the possibility that any of the transition probabilities vanished. It is of interest to know if the picture changes drastically when zero transition probabilities are allowed. In this work we generalized the considerations of ref. [2] to the case where the transition probabilities could vanish, deriving the most general dynamical law which satisfied our generalizations of the physical principles of ref. [2]. We found that this dynamics is similar to that of ref [2]. The transition probabilities are given by the same equations, except that the free parameters which define the dynamics are now allowed to vanish. A unique feature emerges, however, when certain of these free parameters vanish. In this case the development of the universe can abruptly change over to one with completely new values for these parameters, such that each element of the newly growing universe is born to the future of the entirety of the old universe. In more technical terms, we found that our dynamics differs from that of ref. [2] in two ways. One minor difference is that the coupling constants t_n are allowed to vanish, with the corresponding implications on the transition probabilities. The more major difference arises from the vanishing of the 'gregarious' transition probabilities q_n. Each such vanishing heralds the onset of a new era, dubbed a 'turtle', in which a completely new collection of

coupling constants t_n may be used to describe the subsequent sequential growth, and the added condition that each new element that arises is to the future of the entirety of all the previous turtles.

It is interesting to note that, in spite of the fact that a turtle must finish its development at a particular stage in the growth process, it is still compatible with covariance. This is reminiscent of the situation with cosmic renormalization and the formation of posts [6], in that the existence of a post also implies a C-timid future evolution (where C is a causet with a unique maximal element). A key difference however is that cosmic renormalization occurs 'within a single turtle', with a single set of coupling constants. One can show that originary dynamics (e.g. that which occurs after a post) can be identified with a turtle dynamics in which the 'origin element' is a turtle followed by an infinite second turtle.[8] When we consider something like a 'double post', in which C has multiple maximal elements, it is important to note that only the restriction to C-timid causets is compatible with g.c. Causets which attempt to generalize originary dynamics by enforcing a causet with more than one maximal element as a full stem (as suggested in ref. [2]) will violate covariance.

As emphasized in the main body of the paper, the relevant output of any physically satisfactory dynamical law is the specific probability of formation of any causet rather than the transition probabilities of individual transitions. In the case of exclusively non-vanishing transition probabilities, one can be derived from the other, but in the case of possibly vanishing transition probabilities, two dynamical laws differing in their assignations (consistent with the physical principles discussed in section II) of transition probabilities to links emanating from virtual causets still yield the same specific probabilities of formation. Though indeed even the specific probabilities of formation themselves are not physically relevant since they pertain to finite causets formed at a particular stage of the growth process. What is of physical relevance is the resulting probability measure on a suitable space of completed, unlabeled causets [7], or rather sets of such causets to which can be attached a physical meaning. The relevant analysis for the dynamics of ref. [2], showing that indeed such a measure can be defined and characterized in terms of answers to physical questions, has been done

[8] One recovers the originary dynamics described in ref. [6] by choosing the coupling constants of the second turtle $\widetilde{t_n}$ in terms of those of the originary evolution t_n by $\widetilde{t_0} = 1, \widetilde{t_n} = \frac{t_n + t_{n+1}}{t_1}$.

in ref. [7]. The corresponding analysis for the dynamics described in this paper has recently been completed by Dowker and Surya [8]. The key open issue is of course the formulation of the quantum dynamics. It is hoped that our understanding of the most general classical dynamics, in conjunction with the work of ref. [8], may be of some use in the formulation of the quantum dynamics and in investigating aspects of its (semi)classical limit.

DR would like to thank the Williams Watrous Couper Fund for generous travel support, the Raman Research Institute for kind hospitality wherein this work was started, and S. Varadarajan for crucial assistance.

Appendix

Lemma A1: Given any dynamical law consistent with the physical principles of section II, we may set the transition probabilities to zero for any links emanating from any virtual causet. The new dynamical law thus defined is also consistent with the principles of section II and is equivalent to the original one in that it provides the same specific probabilities of formation.

Proof: The proof is trivial since (a) b.c. and the Markov sum rule apply only to real parents, (b) virtual/real causets of the original growth remain virtual/real in the new one, and (c) transition probabilities for links along paths leading from the empty causet to any real causet are unchanged.

Lemma A2: Let C be a causet of cardinality n. Then every path from the empty set to any C-timid causet must pass through C at stage n.

Proof (by contradiction): Suppose there is a path from the empty set to a C-timid causet passing through C' at stage n, with C' not isomorphic to C. Since the final causet is C-timid, C must form at some stage $p > n$. But then there will be $p - n$ elements not in C which are not to the future of every maximal element of C. Hence no such path can exist.

From Lemma A2 it immediately follows that:

(i) No path exists from a C-timid causet to a C'-timid causet where C and C' are non-isomorphic causets of cardinality n.

(ii) No path exists from a causet which is not timid with respect to C and which has cardinality $> n$ to a C-timid causet since, as can easily be verified, the former can be formed along a path not passing through C at stage n.

Lemma A3: If a causet C is C'-timid and has partial stem C'' with C' and C'' both of size n, then $C' = C''$.

Proof (by contradiction): Suppose $C' \neq C''$ in C. Then there exists $x \in C \setminus C'$ such that $x \in C''$. Since C is C'-timid, $\text{past}(x) \supseteq C'$. Since C'' is a partial stem, $\text{past}(x) \subseteq C''$. This implies that $C'' \supseteq C'$ which in turn implies that $C'' = C'$ since they are of the same cardinality.
